## **Acknowledgements**

I would like to thank my advisor Dr. Charles (Buddie) Mullins and Dr. Adam Heller for their support, without which this work would not have been possible. I also would like to acknowledge my fellow group members Melissa Meyerson, Rodrigo Rodriguez, Josh Pender, Ho Hyun Sun, Jason Weeks, Bryan Wygant, and Kenta Kawashima, for sharing their knowledge and technical expertise in helping me to grow as a researcher.

## **Abstract**

# **Controlled Prelithiation of PbS to Pb/Li<sub>2</sub>S for High Initial Coulombic Efficiency in Lithium Ion Batteries**

Yong Guo, M.A.

The University of Texas at Austin, 2018

Supervisor: Charles B Mullins

PbS nanoparticle aggregates were synthesized in a simple aqueous reaction at room temperature, and were tested as a lithium ion anode material, with a gravimetric capacity of 374 mAh/g at C/2, and a 0.15% capacity loss per cycle. However, its half cell initial Coulombic efficiency (ICE) was only 40%, due to a combination of irreversible Li<sub>2</sub>S and solid electrolyte interface (SEI) formations. A custom controlled prelithiation technique was then applied to the PbS electrodes, converting the active material to Pb/Li<sub>2</sub>S, and consolidating the SEI prior to coin cell assembly. This brought the ICE from 40% to >97%, and allowed for immediate cycling of the electrode at high Coulombic efficiency, without further formation cycles. Upon construction of prelithiated Pb/Li<sub>2</sub>S vs NCM full cells, an 82% ICE was observed, with the majority of the lithium loss from the NCM. The full cells had a combined electrode capacity of 100 mAh/g at C/2.

## Introduction

Since its commercialization in the early 1990s, the lithium ion battery has used graphite as its anode material, which is limited to a theoretical capacity of 372 mAh/g, with a lithiated state of  $\text{LiC}_6$ , in a layered configuration<sup>1</sup>. By comparison, other Group 14 elements ( $\text{M} = \text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$ ) can store lithium in a  $\text{Li}_{15}\text{M}_4$  alloy structure, leading to higher capacities of as much as 453 mAh/g for Pb and 3579 mAh/g for Si<sup>1,2</sup>. While silicon has been heavily investigated in the last two decades, lead has received little attention. Lead's heavier weight yields a lower gravimetric capacity. However, its potential for volumetric capacity (Ah/L) rivals that of silicon, at 1937 Ah/L in the lithiated state, more than double that of graphite<sup>1</sup>. Furthermore, lead already has a well-developed recycling infrastructure, resulting in over 99% restoration in North America, stemming from the usage of lead acid batteries in the automobile industry, thus making it environmentally benign<sup>3,4</sup>. Lead is therefore an attractive candidate as an anode material that warrants further investigation.

The major challenge with alloying Group 14 elements is a volume expansion of around 300% during lithiation, compared to that of graphite which is 10%<sup>1,5,6</sup>. This leads to excessive stress on the active material, resulting in rapid capacity loss from particle pulverization, delamination, and continuous parasitic side reactions of electrolyte decomposing onto the active material surfaces, forming a solid electrolyte interface (SEI). Over the last 10 years, various techniques have been used to help alleviate this capacity loss, such as using nanostructures to reduce particle strain, group 16 chalcogenide additives

that act to buffer volume expansion, and carbon coating to passivate particle surfaces, some of which have been applied to lead based anodes <sup>7-14</sup>.

The usage of different group 16 chalcogenides on lead has been demonstrated by Wood and co-workers<sup>7,10,11</sup>. Within this group (O, S, Se, Te), there is a general improvement in performance with increased atomic number, due to greater atomic radii and polarizability, leading to improved electrical and Li<sup>+</sup> conductivity. However, Se and Te are less abundant than S by 4 and 5 orders of magnitude, respectively, making them much more expensive, and less practical for potential commercial use. In turn, using PbS provides a good balance in terms of performance and cost as a potential battery electrode material.

While lead based anodes have been demonstrated in half cells, there has yet to be a full cell study. A major challenge in using PbS in a full cell is the irreversible formation of Li<sub>2</sub>S during its first cycle to Pb/Li<sub>2</sub>S, leading to low ICE. In this study, we eliminate this initial lithium loss by prelithiating the PbS anode, before it is placed inside the coin cell. Various methods of prelithiation on silicon anodes have been demonstrated <sup>15-18</sup>. However, these prelithiation techniques are disadvantaged by two important aspects.

1. The prelithiation is typically performed by direct contact of the electrode with lithium, causing a rapid lithiation that can lead to uneven SEI formation and excess stress on the electrode material. <sup>19,20</sup>
2. The prelithiation is typically done to completion, meaning the fully lithiated anode can only be used with unlithiated cathodes such as sulfur and vanadium oxide

<sup>15,18,21</sup>, and excluded from common commercial lithiated cathodes like LCO, NMC and NCA.

For these reasons, the prelithiation process has to be controlled. Kim, H. *et al.* have demonstrated controlled partial prelithiation on silicon monoxide<sup>16</sup>. We've applied this concept to PbS electrodes, using an improved prelithiation protocol that also serves as an efficient SEI formation step, leading to improved Coulombic Efficiency (CE) in the first cycle, and allowing the electrode to cycle at high CE in a full cell, without additional formation cycles.

## Experimental

### SYNTHESIS OF PbS NANOPARTICLES

1g of  $\text{Pb}(\text{NO}_3)_2$  was dissolved in 50 mL DI water. An equimolar amount of  $\text{Na}_2\text{S}$  was dissolved in another 50 mL of DI water. Under vigorous stirring, the two solutions were quickly mixed, forming a PbS precipitate. After 10 minutes of stirring, the precipitates were centrifuged, and washed three times with 1:1 v/v DI water : ethanol, and dried overnight at  $80^\circ\text{C}$  under vacuum. SEM and XRD characterizations of the PbS were performed using a FEI Quanta 650 and Rigaku R-Axis Spider, respectively. Unused PbS powder was stored under argon, to prevent oxidation.

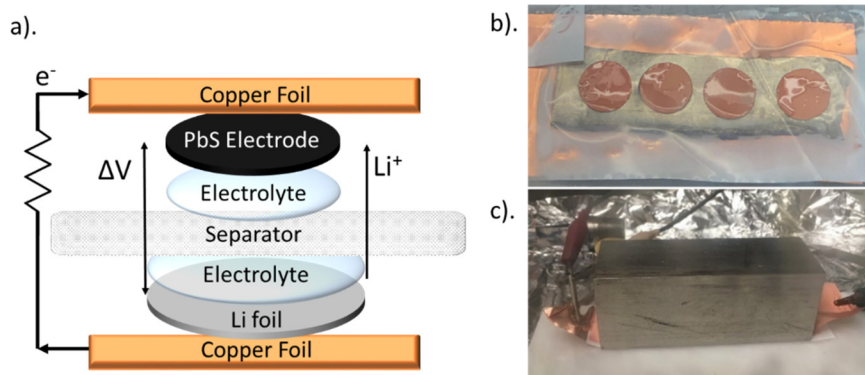

### ELECTRODE PREPARATION:

The active material, carbon additive, and binder weight ratio was kept at 8:1:1 for all electrodes. In a 1.8 mL glass vial, 200 mg PbS was mixed with Timcal Super P, and 6  $\text{ZrO}_2$  pellets of 3 mm in diameter. The active material was dry milled with Super P and  $\text{ZrO}_2$  pellets for 1 minute using a vortex mixer (Fisher Vortex Genie 2) at 10/10 intensity. 1.386 mL of water was added to the glass vial, and the slurry was vortexed at 8/10 intensity for 30 minutes. Carboxymethylcellulose (CMC, 90 kDa, Sigma Aldrich) powder was added, and the slurry was agitated with the vortex mixer at an 8/10 intensity for 30 minutes. Compared to one-step mixing, this multi-step addition improves slurry homogeneity, and reduces agglomeration of Super P and CMC <sup>22,23</sup>. The slurry was then sonicated for 30s in a bath sonicator, to eliminate air bubbles, and then immediately cast onto copper foil using a doctor blade (MTI), at a 50  $\mu\text{m}$  gap and 40 mm/s velocity. The electrode was then dried

under vacuum at 80°C for 6 hours. The resulting electrodes were ~4  $\mu\text{m}$  thick, with 1.0  $\text{mg}/\text{cm}^2$  of PbS mass loading.

#### CONTROLLED PRELITHIATION OF PbS ELECTRODES:

Prelithiation of PbS electrodes was performed inside an argon filled glove box prior to coin cell assembly, as illustrated in Figure 1a. Lead electrodes were stacked in parallel on top of lithium foil (99.9%, 0.75 mm thick, Alfa Aesar), separated by a separator sheet (Celgard). Each side of the separator was wetted by 1:1 v/v. fluorinated ethylene carbonate (FEC) : diethyl carbonate (DEC), with 1M lithium hexafluorophosphate ( $\text{LiPF}_6$ ). Copper foil was placed on both sides to be used as current collectors, while the separator ensured both sides were electrically insulated from each other. An ~2 pound rectangular block was placed on top of the stacked cell, in order to ensure good contact between the layers. The two copper foils were then connected via alligator clips to an Arbin BT-2043 battery tester (Figure 1b and 1c).

*Figure 1: Schematic of prelithiation setup (a). Experimental setup of prelithiation of PbS electrodes with bottom current collector, lithium foil, wetted separator, and 4 PbS electrodes (b). Complete prelithiation setup, with top current collector, a 2 lbs weight, and alligator clips connecting to the Arbin battery tester (c).*

The electrodes were then prelithiated using a modified formation/prelithiation cycling protocol<sup>24</sup>, as shown in Figure 2. Our protocol consists of 3 parts:

1. Full lithiation of the working electrodes at C/5 to 0.01V vs Li/Li<sup>+</sup>
2. 10 short cycles between 0.01 and 0.2V vs Li/Li<sup>+</sup>
3. Full delithiation of the working electrodes to 1.5V vs Li/Li<sup>+</sup>.

At the end of each C/5 cycle, a constant voltage step was applied, long enough for the current to fall below C/20, allowing for a more complete charge/discharge cycle. Upon completion, the electrodes were immediately assembled into coin cells for electrochemical testing.

*Figure 2: Prelithiation/formation cycling protocol used for PbS electrodes. Negative current refers to lithiation of PbS. Protocol consisted of the following: 1). Full lithiation to 0.01V vs Li/Li<sup>+</sup> 2). 10x 0.01-0.2V cycles 3). Full delithiation to 1.5V vs Li/Li<sup>+</sup>. Each C/5 constant current cycle is followed by a constant voltage step, where voltage is maintained until current falls below C/20.*

## **ELECTROCHEMICAL TESTING**

For half cells, 2032 coin cells were fabricated with PbS electrodes, Li foil, polypropylene separators and 1M LiPF<sub>6</sub> 1:1 v/v FEC:DEC, the same electrolyte used during prelithiation. Cyclic voltammetry scans of half cells were performed at 0.1 mV/s between 0.01 - 1.5V vs Li/Li<sup>+</sup>. PbS half cells were constructed, underwent the same prelithiation/formation protocol described earlier, and were cycled 10 times at various C-rates in the following order: C/5, C/2, 1C, 2C, 5C, 1C and C/2. Additional PbS half cells, prepared in the same manner, were cycled at C/2 for 100 cycles. For full cells, PbS electrodes were first prelithiated using the procedure described in the previous section, and were then assembled into coin cells with Li(NiCoMn)<sub>1/3</sub>O<sub>2</sub> (NCM 111), using a 1.05-1.1 N/P (negative/positive) electrode capacity ratio. For comparison, unlithiated PbS electrodes were assembled with NCM into full cells, in the same manner, using a standard C/20 formation cycle. All full cells were then cycled at C/2 for 100 cycles.

## Results and Discussion

### MATERIAL CHARACTERIZATION

Figure 3a shows XRD measurements of the PbS material, indicating the *galena* crystal structure. SEM images of the PbS material show polydisperse nanoparticle aggregates (Figures 3b and 3c). Aggregation likely occurred as a result of the highly spontaneous reaction between  $\text{Pb}^{2+}$  and  $\text{S}^{2-}$  upon mixing.

Figure 3: XRD spectrum of synthesized PbS *galena* (a) and SEM images of PbS nanoparticle aggregates, with scale bars of 100 nm (a) and 1000 nm (b).

### EFFECTS OF PRELITHIATION ON INITIAL COULOMBIC EFFICIENCY

Initial charge/discharge cycles and cyclic voltammetry of non-prelithiated PbS and prelithiated Pb/Li<sub>2</sub>S half cells are shown in Figure 4. Upon initial lithiation of the PbS (non-prelithiated) electrode, sulfur was irreversibly reduced (Figure 4c), leading to a loss of 31-36% in ICE, estimated from the formation of Li<sub>2</sub>S and a fully lithiated state of Li<sub>x</sub>Pb, where  $3.5 < x < 4.5$ <sup>25</sup>. The first lithiation cycle was also characterized by a large baseline current,

attributed to SEI formation, resulting in an overall ICE of only 40% (Figure 4a). By contrast, the prelithiated Pb/Li<sub>2</sub>S electrode show only 3% lithium loss in the first cycle (Figure 4b, 4d). Electrode thicknesses (without current collector) before and after prelithiation were measured with digital caliper to be around 4 and 10  $\mu\text{m}$ , respectively.

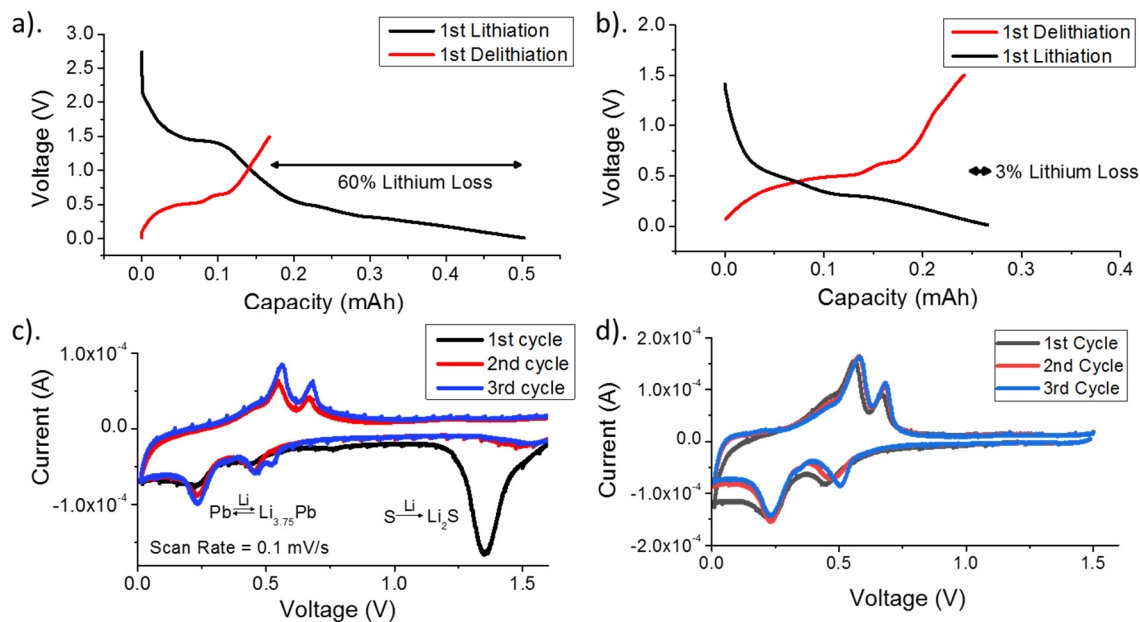

Figure 4: (a) First charge/discharge cycle of the non-prelithiated PbS half cell, (b) first charge/discharge cycle of the prelithiated Pb/Li<sub>2</sub>S half cell, (c) cyclic voltammetry of the non-prelithiated PbS half cell, and (d) cyclic voltammetry of the prelithiated Pb/Li<sub>2</sub>S half cell.

The reason for the 0.01-0.2V cycles during prelithiation/formation was that at near full lithiation, there was a greater abundance of lithium that could react with the electrolyte. As a result, the majority of the SEI would form on the electrode in the lithiated state<sup>26–28</sup>. Figure 5 shows the CE for each 0.01-0.2V cycle was drastically lower than what is expected

from a full 0.01-1.5V cycle. This confirms that a greater percentage of lithium reacted to form the SEI, allowing for more efficient formation cycles.

*Figure 5: Half cell performance of PbS electrode. Cycles 1-10 show the prelithiation/formation process, where the electrode was cycled between 0.01 – 0.2V vs  $\text{Li/Li}^+$ . Normal 0.01-1.5V cycling was then carried out at various C-rates at C/5, C/2, 1C, 2C, 5C, 1C and C/2.*

## HALF CELL PERFORMANCE

Reversible capacities for the PbS electrodes at C/5, C/2, 1C, 2C, and 5C were 410, 367, 337, 305, and 247 mAh/g, respectively (Figure 5). C-rate currents were based on the theoretical capacity of 420 mAh/g for PbS. Upon extended cycling at C/2 (Figure 6), the electrodes experienced 0.15% capacity loss/cycle. The relatively stable cycling of the PbS is attributed to the stabilization of  $\text{Li}_2\text{S}$ , and the semi-porous nature of the nanoparticle

aggregates (Figure 3b-c), which helped accommodate volume expansion <sup>29–33</sup>. The initial Coulombic Efficiency (ICE) of the prelithiated Pb/Li<sub>2</sub>S half cells were 97.5% and 98.8% for C/5 and C/2, respectively (Figures 5 and 6).

*Figure 6: Half cell cycling of Pb/Li<sub>2</sub>S electrodes at C/2 shows 98-99% coulombic efficiency, and average of 0.15% capacity fade per cycle*

## FULL CELL PERFORMANCE

Prelithiated Pb/Li<sub>2</sub>S electrodes were put inside full cells with NCM (111) cathode electrodes, and cycled at C/2. The capacity ratio between the negative and positive electrodes (N:P ratio) was kept between 1.05-1.1 for all full cells, in order to prevent Li plating on the anode. Figure 7a shows full cell performances of prelithiated Pb/Li<sub>2</sub>S electrodes, compared to the performance of non-prelithiated PbS electrodes. Initial

electrode capacities at C/2 were 374 mAh/g for Pb/Li<sub>2</sub>S (Figure 6), and 140 mAh/g for NCM (Figure 7), resulting in a combined full cell capacity of 102 mAh/g (Figure 8a). The ICE of the prelithiated full cells cycled at C/2 was 82.0% (Figure 8b). The majority of this lithium loss is attributed to the NCM cathode, which generally has an 85% ICE (Figure S-2) <sup>34</sup>. By contrast, the ICE of the unlithiated PbS full cells, which used a standard C/20 formation cycle, was only 20% (Figure 8b and d), even lower than the 40% observed in unlithiated PbS half cells. This is because the redox potential of sulfur is much higher than that of lead (Figure 4c), such that the first charge cycle was more selective towards lithiating sulfur instead of lead. A much larger cathode would be required in order to fully lithiate the non-prelithiated PbS electrode. Following the first cycle, the CE of the prelithiated Pb/Li<sub>2</sub>S electrodes normalized to 98-99% within 2 cycles, while the CE of the unlithiated PbS electrodes reached 98% after 20 cycles (Figure 8b).

Figure 7: Cycling performance of NCM 1:1:1 vs Li half cells at C/2, after a C/20 formation cycle, showing 140 mAh/g initial reversible capacity, reaching 99.5% coulombic efficiency within the first 10 cycles.

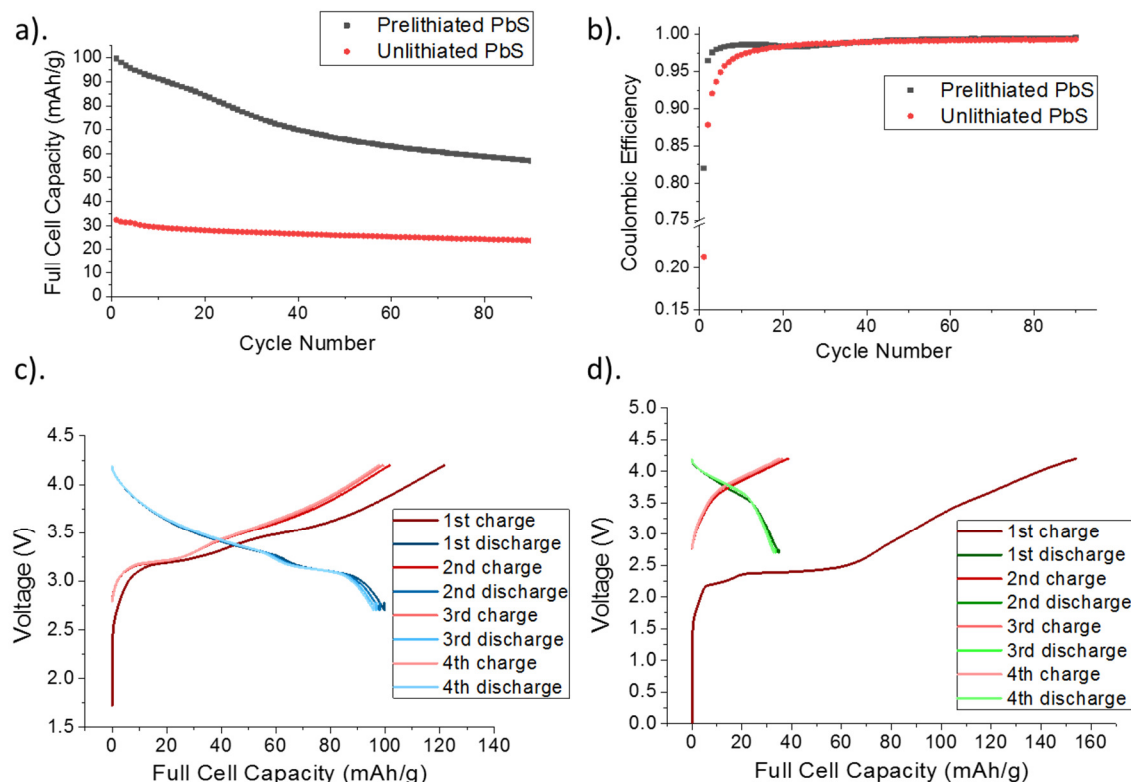

Figure 8: Combined electrode capacities of prelithiated Pb/Li<sub>2</sub>S-NCM full cells and unlithiated PbS-NCM full cells, cycled at C/2 (a), and their respective Coulombic Efficiencies (b). Charge/discharge curves of full cells with prelithiated Pb/Li<sub>2</sub>S electrodes (c), and charge/discharge curves of full cells with unlithiated PbS electrodes, with first charge being a C/20 formation cycle (d)

## POST-MORTEM ANALYSIS

After cycling, Pb/Li<sub>2</sub>S half cells were completely delithiated to 1.5V vs Li/Li<sup>+</sup> and disassembled. Bright Field (BF) and Dark Field (DF) STEM scans of the cycled electrode shows two segregated phases within the electrode material, believed to be Pb and Li<sub>2</sub>S

(Figures 9e, 9f, 10b, 10c). Pb, having a much higher atomic number than Li or S, would be depicted as a brighter region under a DF scan.

*Figure 9: SEM, BF and DF STEM (a-c, respectively) scans of PbS nanoparticle aggregate before cycling. SEM, BF and DF STEM (d-f, respectively) scans of Pb/Li<sub>2</sub>S electrode material after 200 cycles. Scale bar represents 200 nm for all images.*

*Figure 10: SEM (a), BF (b) and DF (c) scans of Pb/Li<sub>2</sub>S electrode material after 200 cycles. Scale bar represents 200 nm. The circled nanoparticles of ~50 nm in diameter is believed to be a Timical Super P nanoparticle.*

## Conclusion

For the first time, full cells were created with a lead based anode, using PbS. The cells were tested employing two different types of lead sulfide anodes: (i) a lead sulfide anode that was prelithiated to create a composite active material Pb/Li<sub>2</sub>S and (ii) a PbS active material that was not prelithiated. The controlled prelithiation protocol used not only improved the half cell ICE from 40% to >97% (compared the non-prelithiated anode), but also helped form a stable SEI layer, which allowed the electrodes to perform at high CE, without additional formation cycles. The prelithiated Pb/Li<sub>2</sub>S electrodes showed a 374 mAh/g half cell capacity at C/2, and a combined electrode capacity of 102 mAh/g capacity when cycled with an NCM cathode.
